Hospital-acquired urinary tract infection point prevalence in Turkey: Differences in risk factors among patient groups

Meltem Isikgoz Tasbakan^{1*}, Raika Durusoy², Husnu Pullukcu¹, Oguz Resat Sipahi¹, Sercan Ulusoy¹ and 2011 Turkish Nosocomial Urinary Tract Infection Study Group

Abstract

Background: The aim of this study was to determine the point prevalence of nosocomial urinary tract infections (UTIs) and to investigate risk factors for pathogen type (*E. coli* vs. others) and extended-spectrum beta-lactamase (ESBL) positivity among nosocomial UTI patients.

Methods: A questionnaire consisting of 44 questions on demographic data and risk factors of UTI cases was sent to 51 tertiary care hospitals. Univariate and multivariate analyses were conducted.

Results: The overall prevalence of UTI was 1.82% (483/26534). The prevalence of UTI was higher in intensive care units (ICUs) with 6.77% versus 1.45% outside ICUs. Hospitals of the Ministry of Health (compared to university hospitals), hospitals in less developed provinces and hospitals with bed capacity < 500 had higher UTI prevalence. Patients without a urinary catheter were more likely to have received immunosuppressive therapy, current corticosteroid use, renal transplantation and uterine prolapsus and less likely to have another infection outside the urinary tract, as compared to catheterized patients. Among the 422 culture-positive patients, the most common pathogen was *E. coli* (45.5%). The risk factors increasing the likelihood of *E. coli* in urine culture were being female, history of urinary tract operation, no use of antibiotics in the preceding three months and infection outside the urinary tract. There were 247 patients with *E. coli* or *Klebsiella spp.* positive in culture. Among these, 61% (n=151) were ESBL- positive. Among patients having *E. coli*/*Klebsiella* positive in culture, antibiotic use in the preceding three months and history of urinary tract operation were the independent risk factors significantly increasing the risk of ESBL.

Conclusions: The reasons underlying the high prevalence of nosocomial UTIs, and a better understanding of the risk factors might lead to improved control of these infections.

Keywords: Urinary tract infection, Nosocomial infections, *Escherichia coli*, Point prevalence, Epidemiology

Introduction

Urinary tract infection (UTI) is the most commonly encountered hospital-acquired infection and the major risk factor is urinary catheterization [1]. According to reports from Turkey, 21-49% of hospital-acquired infections are urinary tract infections [2]. In a multi-center point prevalence study conducted in Turkey in 2001 where the same case definitions were used, the prevalence of hospital-acquired urinary tract infections had been reported as 1.7%

among 13269 patients from 29 centers [3]. The importance of nosocomial infections has increased in the last decade and establishment of hospital infection committees and surveillance of nosocomial infections have become mandatory since 2005 for all the hospitals in Turkey [4]. In this multi-center point-prevalence study, it was aimed to determine the prevalence of hospital-acquired UTI among inpatients and to investigate risk factors determining pathogen type (*E. coli* vs. others) and extended-spectrum beta-lactamase (ESBL) positivity among nosocomial UTIs.

Patients and methods

A questionnaire consisting of 44 questions was prepared to investigate demographic data (gender, age), risk factors, catheter use and characteristics of rooms of patients who had UTI (Additional file 1). The latest version of this form was given to two independent experts outside the study team for their expert views. The questionnaire reached its final version after a pilot study conducted in Ege University. The study was approved by the local ethics committee.

Inclusion criteria: Patients aged 18 years and above were included in the study. Cases having at least one of the symptoms like fever ($> 38^{\circ}\text{C}$), pollakiuria, dysuria, suprapubic tenderness and having $\geq 10^5$ CFU/ml of one or two types of bacteria or culture-negative patients having at least two of the above-mentioned symptoms and one of the seven criteria defined by Centers for Disease Control and Prevention like nitrite test positivity, pyuria were included in the study [5]. All the cases were diagnosed by infectious diseases specialists. Asymptomatic patients were excluded.

Study design: A list of all public tertiary care hospitals in Turkey, i.e. University Hospitals and Training and Research Hospitals of the Ministry of Health, was obtained from the Ministry of Health Department of Inpatient Institutions' statistical yearbook. Special branch hospitals like pediatric, ophthalmologic hospitals etc. were excluded. In total, 71 general tertiary care hospitals comprised the target group and 51 accepted to participate in the study (71.8% coverage; three rejected participation and the others did not respond or could not be contacted). The questionnaires and a data-entry spreadsheet were sent by e-mail to the participating specialists who formed the study group. The point-prevalence survey was conducted on 28 September 2011, based on all the nosocomial UTI cases who were present on the wards of the hospital on that day. All the wards in the participating hospitals were visited by the study group, questioning about patients with UTI symptoms. Patient data were collected by the detailed standard questionnaires, entered electronically to the spreadsheet and sent by each participating centre to the organizing centre via e-mail.

Statistical analysis

Data were analyzed centrally. The total, intensive care unit (ICU) and non-ICU prevalence rates of each hospital was calculated using the number of UTI cases and the number of total, ICU and non-ICU beds occupied in that hospital on the survey date. The overall hospital-acquired UTI prevalence was calculated along with its 95% confidence interval (CI). Prevalences in ICUs and non-ICU wards were compared with paired samples t test. The provinces of the hospitals were classified according to the State Planning Organization's 2011 developmental ranking [6]. The possible impacts of institution (Ministry of Health vs. university),

bed capacity (< 500 vs. ≥ 500) and the province's developmental level (the most developed 10 provinces vs. others) on the UTI prevalences of hospitals were analysed with Mann-Whitney U test, and the prevalence outside ICUs was compared according to institution using Student's t test. Univariate analyses on the impacts of risk factors on the type of organism (*E. coli* vs. others) and the presence of ESBL among patients with *E. coli* or *Klebsiella spp.* in urine culture were conducted with the chi-square test. All the variables with a significant impact in univariate analyses were then entered into a multivariate logistic regression model. Odds ratios are presented with 95% confidence intervals. A p value less than 0.05 was considered as significant.

Results

Data were collected from 51 tertiary care hospitals located in 29 out of 81 provinces of Turkey. The overall prevalence of UTI was 1.82% ($n=483$, 95% CI 1.819-1.822) according to our survey conducted in 51 hospitals comprising 26534 occupied beds in total, with a range between 0.00-5.26% among individual hospitals. The prevalence of UTI in ICUs was 6.77% ($n=127$; 95% CI 6.759-6.782) with the range 0.00-32.26% among different hospitals and 1.45% ($n=356$; 95% CI 1.445-1.448) outside ICUs, with a range of 0.00-4.90% among different hospitals.

Overall, ICU and non-ICU UTI prevalence in hospitals in less developed provinces and hospitals with < 500 bed capacities was significantly higher. Hospitals of the Ministry of Health had a higher overall prevalence of UTI as compared to University Hospitals, while their ICU prevalence was much higher but non-ICU prevalence significantly lower than university hospitals (Table 1). Two hospitals did not have any UTI cases. The mean number of nosocomial UTI per hospital was 9.5 ± 7.4 (range 0-34; median 7), with a total of 483 UTI cases on the survey date.

The mean age of the patients was 59.1 ± 18.3 (range 18-96), with 53.6% ($n=260$) ≥ 60 years and 51.3% ($n=248$) female. Among these, 63.4% ($n=306$) were hospitalized in non-surgical (medical) departments vs. 36.6% ($n=177$) in surgical departments and totally 26.1% ($n=126$) were in the ICUs of the departments. Except 12 patients, all patients had at least one risk factor for UTI. The prevalence of each risk factor surveyed is shown in Table 2, stratified and compared according to the catheter status.

Among the UTI cases, 309 had a urinary catheter. Catheterization was performed by a doctor in 261 patients (85%), by a nurse in 32 (10%), undergraduate intern doctor in 5 (2%), the patient himself in 6 (2%), and the catheterization team in one patient (0.3%). Among patients having a urinary catheter, only one was on day 0, four were on the 1st day and 17 on the 2nd day of their catheter. The distribution of patients according to the length of time the catheter remained in situ is shown in Table 3 along with other characteristics of catheterized patients.

Table 1 UTI prevalence among different hospital types and units

Categories	Number of hospitals	Overall UTI prevalences (95% confidence intervals)					
		Total no. of patients / Total no. beds	Overall prevalence	ICU patients	ICU prevalence	Non-ICU patients	Non-ICU prevalence
Institution							
Ministry	15	143 / 7526	1.900 (1.897-1.903)	46 / 559	8.229 (8.206-8.252)	97 / 6967	1.392 (1.390-1.395)

Table 2 Predisposing factors for urinary tract infections (UTIs) * (n=483)

Risk factor	Urinary catheter		Total n (%)
	Present (309) n (%)	Absent (174) n (%)	
Antibiotic use in preceding 3 month	220 (71.2)	118 (67.8)	338 (70.4)
UTI in the preceding year	127 (41.1)	80 (46.0)	207 (43.3)
Infection outside the urinary tract	131 (42.4)	35 (20.1)	166 (34.4)
Diabetes mellitus	80 (25.9)	51 (29.3)	131 (27.1)
Chronic renal failure	65 (21.0)	37 (21.3)	102 (21.2)
Immunosuppressive therapy in preceding 6 month	43 (13.9)	46 (26.4)	89 (18.4)
Urinary tract operation in preceding 6 month	55 (17.8)	33 (19.0)	88 (18.3)
Prostate hypertrophy	49 (15.9)	32 (18.4)	81 (16.6)
Current corticosteroid use	41 (13.3)	35 (20.1)	76 (15.8)
Urinary tract anomaly	39 (12.6)	19 (10.9)	58 (12.0)
Urethral stent	17 (5.5)	6 (3.4)	23 (4.8)
Urinary reflux	9 (2.9)	8 (4.6)	17 (3.5)
Renal transplantation	3 (1.0)	14 (8.0)	17 (3.5)
Uterine prolapsus	3 (1.0)	8 (4.6)	11 (4.4)

*Some patients had more than one predisposing factor.

Among the patients, 24.0% were staying in single rooms, 24.4% in double rooms and the remaining in rooms with three or more patient beds. A hand disinfectant was present in 77.0% of the patient rooms and 45.6% had a private toilet in the room.

Among the 483 patients with UTI, urine culture specimens were tested for 477 patients, of whom 467 had

complete information on the urine culture results, 9.6% (n=45) being negative. Among the 422 culture-positive patients, the five leading microorganisms were *E. coli* 45.5% (n=192), *Candida spp.* 15.9% (n=67), *Klebsiella spp.* 13.3% (n=56), *Enterococcus spp.* 10.2% (n=43) and *Pseudomonas spp.* 10.0% (n=42). Of culture-positive patients, 4.9% (n=21) had mixed infection with two microorganisms simultaneously in the urine culture.

We explored the impact of UTI and other risk factors on the presence of *E. coli* –the leading microorganism in the study group with 45.5%– vs. other microorganisms in urine or blood culture. Significant risk factors are shown in Table 4. The mean age of patients with *E. coli* and patients with other microorganisms did not differ significantly. Other non-significant risk factors were: type of ward (internal vs. surgical), UTI in the preceding year, current corticosteroid use, immunosuppressive therapy in the preceding 6 months, diabetes mellitus, chronic renal failure, renal transplantation, prostate hypertrophy, urinary reflux and urethral stent.

There were 247 patients with *E. coli* or *Klebsiella spp.* positive in culture. Among these, 61% (n=151) were ESBL-positive. The associations between known UTI risk factors on ESBL were explored and the significant associations are presented in Table 5. There was no difference in the mean age of ESBL positive and negative patients (58.0 ± 18.4 and 59.4 ± 19.0 years, respectively, $p=0.590$). Type of ward (medical vs. surgical), clinic (ward vs. ICU), presence of toilet in patient's room, hand disinfectant in patient's room, number of patient beds in the room, UTI in the preceding year, current corticosteroid use, immunosuppressive therapy in the preceding 6 months, diabetes mellitus,

*p< 0.00.

chronic renal failure, renal transplantation, urinary tract anomaly, prostate hypertrophy, urinary reflux, infection outside the urinary tract, catheter in the urinary tract and urethral stent did not have a significant impact on the presence of ESBL among patients having *E. coli/Klebsiella spp.* positive in culture.

Blood culture was performed in 308 of the cases, of which 101 (32.8%) yielded an etiologic agent. In 38 patients, the same microorganism was positive in both urine and blood culture. The five leading micro-organisms found in blood cultures were *E. coli* (22), *Candida spp* (18), *Klebsiella spp* (12), *Acinetobacter spp* (12) and *S. aureus* (10).

In 165 patients, the presence of a simultaneous infection at another site was determined. Among these, 78 patients had pneumonia, 26 had soft tissue infection, 25 bacteremia, nine had surgical site infection, six gastroenteritis, five

candidemia, four infective endocarditis, three septicaemia, two meningitis and one had herpes keratitis. Six patients had multiple infectious foci.

Discussion

Determination of their prevalence and risk factors are keys to the prevention of hospital acquired urinary tract infections. The first point prevalence study carried out in 2001 in Turkey had found UTI prevalence as 1.7% [3]. Our present study, which was conducted ten years later, has included more than twice hospitals and patients and has found a prevalence of 1.82%. Sartor et al. had found a decrease in UTI prevalence from 1.8% to 1.1% in the point prevalence study they had repeated five years apart [7]. Askarian et al. have reported a UTI prevalence of 1.4% in their one-day point prevalence study they had

Table 5 The impact of UTI and other risk factors on the presence of ESBL among patients having *E. coli/Klebsiella spp.* positive in culture (n=247)**

Risk factor	Categories	n	ESBL+ n (%)	Univariate p	Multivariate OR (95% CI)
Gender	Male	118**	80 (67.8)	0.032	1.12 (0.69-1.82)
	Female	130**	71 (54.6)		1

*p< 0.005 **One case had mixed infection with *E. coli* and *Klebsiella spp.*

repeated in four different days [8]. A decrease in the hospital acquired UTI prevalence could have been anticipated in Turkey, due to the recent legal implications. Considering the shortage of physicians, nurses and other health staff due to economic constraints, the stability of the UTI prevalence instead of an increase could be considered as the success of the infection control legislation. However, much more efforts are needed to reach the target of zero infection rates.

The prevalence of UTI is higher in ICUs. A study from Scotland has also found a significantly higher prevalence in ICUs (27.1% vs 9.3%) [9]. The most common reason of this higher prevalence is the application of catheters [10]. There is especially a link between the length of time the catheter remained in situ and the development of infection [11]. In our study, the very low number of patients on day 0–2 of the catheter (7.2%) and the high majority of patients on ≥ 3 days (92.8%) is in concordance with this well established link.

The total ICU and non-ICU prevalence rates were affected by hospital type, developmental level of the province and hospital size. While no significant difference was found according to the number of beds in the first point prevalence study conducted in Turkey in 2001, the point prevalence in hospitals with < 200 beds was much higher than the larger hospitals (2.8% vs. 1.4–1.7%) [3]. Our study has found a significantly higher prevalence in hospitals with < 500 beds as compared to hospitals with 500 beds and over. This might be related to less severe hospital infection control protocols in smaller-scale hospitals. As for type of institution, the lower overall prevalence found in university hospitals might be due to better infection control measures, especially in ICUs, but the higher prevalence in non-ICU wards might be attributed to the hospitalization of more complicated patients in university hospitals. The significantly lower prevalence in the most developed 10 provinces of Turkey might be due to more favorable economic conditions of the hospitals.

The most common risk factors identified in our study were the use of antibiotics in the preceding three months, urinary catheter, UTI in the preceding year and diabetes, in concordance with previous studies [12].

Enterobacteriaceae includes the most common pathogens associated with UTI. Other predominant pathogens are *Candida* species, *Enterococci* and *P. aeruginosa*. In another multi-national (including Turkey) and multi-center study, a total of 1762 isolates were collected from 38 centers in 11 countries from patients with UTIs in 2009 and 2010. *Enterobacteriaceae* comprised 86.0% of the isolates, of which *E. coli* (56.5%) and *K. pneumoniae* (13.8%) were the two most common species [13]. The most common pathogen in our study was *E. coli* as well, with 45.5%. The risk factors increasing the likelihood of *E. coli* in urine culture were female gender and urinary tract operation

in the preceding six months. Female gender is an already established risk factor for community-acquired UTIs. Male gender, antibiotic use in the preceding three months and having an infection outside the urinary tract were significant risk factors increasing the likelihood of contracting other microorganisms than *E. coli* in the culture. Some other risk factors that were significant in univariate analyses lost significance in multivariate analyses. To our knowledge, this study is the first exploring risk factors that determine the pathogen type in UTIs.

Candida spp. was the second most common pathogen in our study with 15.9%. Yeasts that were the third most common pathogens in the point prevalence study conducted 10 years ago have risen to the second position. Many studies indicate that at least 10%–15% of hospital acquired UTIs are caused by *Candida* species. Candiduria is especially common in ICUs and may represent the most frequent UTIs encountered in adult surgical ICUs [14]. In a multi-center study conducted in ICUs in Turkey, the most common pathogen in catheter-associated UTIs were *Candida* species with 44.9% [15]. The fact that our patients had a high rate of antibiotic use and the high prevalence of ≥ 3 days urinary catheterization might have affected this outcome. The rise in the proportion of yeasts in catheterized patients merits special attention.

Antimicrobial resistance is increasing in bacteria isolated from both nosocomial and community-acquired UTIs [3]. ESBL-producing *E. coli* and *K. pneumoniae* are increasingly becoming of concern in many parts of the world [16]. The rise of ESBL positivity observed in Turkey has also been shown in this study [17]. Antibiotic use in the preceding 3 months and urinary tract operation in the preceding 6 months were significant risk factors for ESBL among patients positive for *E. coli* or *Klebsiella* spp, both of them being already established significant risk factors in the literature [18]. The increased risk in male gender in univariate analyses disappeared after adjustment, which might show bias due to the increased risk of urinary tract operations compared to women in univariate analyses.

Table 6 Published hand washing data in the study centers

(n: Hand washing observation).

Since 2006, when the national hospital infection surveillance system was established and surveillance became mandatory, all of the hospitals in Turkey have been reporting their hospital infection rates to the Ministry of Health. The government and Turkish Society of Hospital Infections and Control started quality control studies and educational programs in all regions of Turkey [19]. These relatively low rates of UTIs which are comparable with previous studies carried out in Iran and France can also be the result of educational and infection control programs [7,8].

Hand washing is a very important and cheap method for improving the hospital infection rates. Although there are not data related to the all study centers, the published hand washing studies from some of the study centers (Table 6) report a compliance rate of maximum 40%. Hence, hand washing compliance is poor and needs to be increased in most parts of Turkey [20-25].

The most important limitation of this study is the lack of a control group, which could have enabled a clearer understanding of risk factors of hospital acquired UTI. Another limitation is the one-day duration of the study, which enabled only the recording of the ESBL ratio of the microorganisms found in urine cultures to the questionnaire.

In conclusion, the reasons underlying the high prevalence of nosocomial UTIs, which has not ameliorated in 10 years' time despite the new legislation and its application should be investigated. A better understanding of the risk factors might lead to improved control of these infections.

Submit your next manuscript to BioMed Central and take full advantage of:

- Convenient online submission
- Thorough peer review
- No space constraints or color figure charges
- Immediate publication on acceptance
- Inclusion in PubMed, CAS, Scopus and Google Scholar
- Research which is freely available for redistribution
